Abstract: This study analyses self-rated health and non-employment and potential synergy effects among lone and couple mothers aged 25-59 in Britain, Sweden and Italy, representing different family policy categories using data from national surveys (2000-2005). Synergy effects on health were calculated by synergy index. Non-employment only marginally contributed to the excess risk of poor health among lone mothers but there were synergy effects between lone motherhood and non-employment in all three countries, producing a higher risk of poor health than would be expected from a simple addition of these exposures. Results are discussed in relation to the different family policy and living contexts.

Responses to reviewer # 3's comments:

- The title would read better if "contribute to" is replaced by "associated with". Consider also omitting the subtitle.

**Response:** We have changed the title accordingly, and altered the subtitle. The new title reads: "Is non-employment associated with the health disadvantage among lone mothers in Britain, Italy and Sweden? Family policy and synergy effects"

- Avoid causal arguments and terminology throughout the text ("causal", "impact", "effect" etc.).

**Response:** We have searched the text for causal arguments and terminology, and changed the wording where we thought it appropriate, and kept the wording when referring to other studies where this terminology has been used.

- Use "employment" instead of "work" wherever appropriate.

**Response:** We have gone through the article and change wherever appropriate.

- The country specific analyses have been separately conducted and therefore avoid direct comparisons of countries in terms of the levels of risk (OR). Interactions would be needed for direct country comparisons.

**Response:** We agree and have made alterations in the text.

- The second para of Discussion says "Non-employment only partly explained.". In my mind the explanation was minimal.

**Response:** We agree and have changed this to: "Non-employment only marginally contributed to the excess risk..."

# Is non-employment associated with the health disadvantage among lone mothers in Britain, Italy and Sweden? Family policy and synergy effects

## Abstract

This study analyses self-rated health and non-employment and potential synergy effects among lone and couple mothers aged 25-59 in Britain, Sweden and Italy, representing different family policy categories using data from national surveys (2000-2005). Synergy effects on health were calculated by synergy index. Non-employment only marginally contributed to the excess risk of poor health among lone mothers but there were synergy effects between lone motherhood and non-employment in all three countries, producing a higher risk of poor health than would be expected from a simple addition of these exposures. Results are discussed in relation to the different family policy and living contexts.

## Key words:

Single parent, welfare state, family policy, poor health, employment

## Introduction

Combating poverty and increasing the standard of living among disadvantaged groups is a basic purpose of developed welfare states. Lone mothers, being an economically vulnerable group of women, have been proposed as a litmus test as to how family policy regimes operate (Burstrom, Whitehead et al. 2010). This article builds on our previous study of health inequalities between lone and couple mothers in different family policy regimes (Burstrom, Whitehead et al. 2010), and adds sub-group analysis of a particularly vulnerable group of the lone mothers; the non-employed.

As Bambra and Eikemo (2009) recently showed, the associations between employment status and health play out differently in different countries. Several studies have found positive health effects of combining employment and family for women, including lone mothers

1 (Fokkema 2002; Lahelma, Arber et al. 2002; Artazcoz, Borrell et al. 2004; Zabkiewicz 2010).  
2 Just as unemployment has been associated with worse physical and mental health (Bartley,  
3 Ferrie et al. 2006), and with negative health behaviours such as smoking (Waldron and Lye  
4 1989), women who are keeping house full time are more likely to report ill health, compared  
5 to those in employment (Bartley, Ferrie et al. 2006). Studies have shown that there may be  
6 health selection into non-employment (Jusot, Khlat et al. 2008).  
7  
8  
9

10  
11  
12 However, the relation between employment and health may be different among men and  
13 women, in different social groups, and in different national contexts, where the meaning of  
14 paid employment may vary because of norms, values and policies. Family policy  
15 encompasses policies for reconciling employment and parenthood (Gornick and Meyers  
16 2003). These are of particular salience to parents with dependent children, and especially for  
17 lone mothers. Labour market opportunities for women vary between different welfare systems  
18 and by social groups, and these country differences are further related to family policy. For  
19 example, in countries with “earner-carer” (dual earner) policies, employment rates are higher  
20 among women with low or medium education than in countries with “market-oriented” and  
21 “traditional-family” policies (Korpi, Ferrarini and Englund 2011).

31  
32 Drawing specific examples of distinctive family policy categories from the Korpi et al  
33 typology, we analyse country level data from countries where we have in depth knowledge of  
34 the policy framework and living conditions among lone mothers. In this study, we aim to  
35 compare health and non-employment experiences of lone and couple mothers in different  
36 social positions in Britain, Sweden and Italy. We analyse empirically the social characteristics  
37 and composition of lone motherhood, exposures to non-employment, the association between  
38 non-employment and health and calculations of synergy effects between non-employment and  
39 lone motherhood on health. Finally we discuss the observed findings in relation to policy and  
40 living conditions for lone mothers in each country. As there are relatively few lone fathers in  
41 our datasets and both the explanations for poor health and the employment policy context are  
42 likely to differ for men and women, we have not included lone fathers in the study presented  
43 here, but they are the subject of future studies.

As arrangements differ widely between countries, various welfare state typologies have been proposed, including the most recent models based on institutional structures of relevance for both gender inequality and class inequality that take special account of the expansion of family policy and its effects on the lives of women (Korpi 2000; Ferrarini 2006; Lundberg, Åberg Yngwe, et al 2008; Ferrarini and Norström 2010). Family policies are multidimensional and reflect conflicting political forces as well as religion. The main distinction is made by whether they favour traditional families, market reliance or mother's employment. This typology groups countries similarly to the well-known overall welfare typology of Esping-Andersen (1990). The difference however, is that the focus here solely is on institutional dimensions of family policy.

Figure I illustrates the categorisation of family policy along two dimensions: the degree to which policy supports a traditional, nuclear family (where benefits, tax relief and leave entitlements support the father as the main breadwinner and the mother to stay at home to care for children) and the degree to which policy supports a dual-earner family. The exact operationalization of the model is spelled out in detail in Ferrarini and Norström (2010). The categorisation of countries should not be regarded as fixed, but may change as policy shifts. Below we discuss what outcomes the institutional differences in family policy have in terms of arrangements for employment and parenting for mothers in our chosen countries.

**Figure I. Dimensions and models of family policy around the year 2000. Adapted from Korpi 2000, Ferrarini 2006 and Ferrarini and Norström 2010**

In this typology, Britain falls into the ‘Market-oriented model’ with lower levels of support in both dimensions, leaving families to deal with family support and childcare privately through the market. Traditionally, employment rates have been low among mothers in Britain, especially among lone mothers, who have received financial support to stay at home with their children. Since the late 1990s and until recently, however, a range of social and employment policies have been introduced to support maternal employment (Cebulla, Flore et al. 2008; Lewis, Knijn et al. 2008) and these efforts have increased employment rates of lone mothers. Flexible employment and family friendly policies have been introduced through legislation and both maternal and paternal leave and benefits have been improved albeit from a comparatively low level (La Valle, Clery et al. 2008). At the same time, there was extensive investment in making childcare more available and affordable, with the National Childcare Strategy introducing 15 hour per week of free early years education for three and four year olds and a subsidy for childcare for working low and middle income families (La Valle, Clery

1 et al. 2008). Child care for children aged below three is generally provided by parents,  
2 grandparents or child-minders (Lewis, Knijn et al. 2008). Whilst these reforms have had a  
3 positive effect on lone mothers employment (Gregg, Harkness et al. 2009), the limited  
4 provision of low-cost, flexible childcare for low income parents, and lone mothers in  
5 particular, remains a barrier to employment (Finch 2008; LaValle and Smith 2009).  
6  
7  
8  
9

10 Italy falls into the ‘Traditional family policy model’, orientated towards preserving traditional  
11 family patterns with highly gendered divisions of labour within families. Tax benefits for a  
12 working male with a dependent partner and flat-rate childcare leave benefits encourage  
13 mothers to stay at home. Family and relatives are expected to provide support and the welfare  
14 state has only a residual role to tackle very critical situations, when individuals and families  
15 are poor in a manifest way and are entitled to become public assistance recipients. Negative  
16 attitudes towards mothers’ employment are more prevalent than in the other policy categories  
17 (Korpi 2000). As in the rest of southern Europe, women tend either not to work at all, or work  
18 full-time and continuously, and lone mothers are often in the latter category (Orloff 2002;  
19 Sabbadini 2006). Childcare in Italy is generally high in quality, but availability is limited and  
20 heterogeneous across regions, and offers low flexibility in hours of service (Del Boca and  
21 Vuri 2007). Family support is thus necessary, and the availability of informal childcare  
22 increases the probability of mothers’ employment (Del Boca and Vuri 2007). It is especially  
23 common that grandmothers mind children aged below three, for whom child care is not  
24 readily available (Naldini and Saraceno 2008). The downside to informal childcare is family  
25 dependency for lone mothers (Solera 1998).

41 Sweden falls into the ‘Dual-earner model’, encouraging both fathers and mothers to work  
42 through family-friendly employment policies (including generous parental leave and  
43 possibilities to reduce work hours) and subsidized universal pre-school childcare provision.  
44 The employment rates of mothers including lone mothers’ in Sweden are thus among the  
45 highest in Europe. However, the employment rate among lone mothers has declined during  
46 the last decade. Childcare in Sweden is generally considered to be of high quality and  
47 affordable, fees are income related (with a low ceiling) and heavily subsidised and available  
48 full time from the child’s first birthday (Ferrarini and Duvander 2010). Recent changes in  
49 family policy includes the implementation of the “daddy-months” in the parental leave  
50 system, but also a flat rate home care allowance that allows a parent to stay home and tend to  
51 small children and receive a relatively low monthly allowance for this (Ferrarini and

1 Duvander 2010). These observed differences between the countries might suggest that the  
2 relationship between lone motherhood, non-employment and health might vary.  
3  
4

### 5 *Lone motherhood, non-employment and health* 6 7

8  
9 Lone motherhood is associated with worse health in all three countries (Burstrom, Whitehead  
10 et al. 2010). Three main pathways to ill health have been proposed in the literature: material,  
11 behavioral and psychosocial pathways (Marmot 2006). Discussing how non-employment may  
12 be related to poor health among lone mothers, the material aspect is important. Studies have  
13 shown that household labour market attachment has become increasingly important for  
14 alleviating poverty risks (Fritzell and Ritakallio 2010). In many welfare systems, employment  
15 also generates eligibility for welfare resources. Being non-employed could result in poverty,  
16 which may affect health in several ways. Besides the direct effect of material scarcity, the  
17 alienation from society and stigma also affect health (Reid and Tom 2006). This relates to the  
18 psychosocial pathway.

23  
24  
25  
26  
27

28  
29 As noted by many researchers, life styles and health behaviours such as smoking, lack of  
30 exercise, poor nutrition etc. are strongly linked to social position, and as such are more  
31 prevalent among persons with low education and the unemployed and among lone mothers in  
32 some countries. Non-employment in this study is regarded as a potential explanatory factor in  
33 the association between lone motherhood and poor health. As noted, mothers' employment  
34 rates vary between the countries. There are many reasons for women's economic inactivity,  
35 which may also differ between countries. A study analysing women's disconnection from the  
36 labour market in England showed that (excluding students) this group included: full time  
37 homemakers; retired people; those who are not in employment because of long term illness or  
38 disability; and those who were seeking employment but were not available for work in the  
39 next two weeks (Grant 2009). Of those who are economically inactive, there may be a large  
40 proportion who want to work, but who are restrained from doing so (Grant 2009). We also  
41 distinguish a group that is economically active but not employed; the unemployed. The 'non-  
42 employed' category is therefore made up of three main groups: people of working age who  
43 are available for employment and actively seeking employment but without jobs, labelled  
44 'unemployed'; people of working age who are not available for employment and not seeking  
45 it due to a variety of reasons: for example permanent sickness, early retirement, students in  
46 education, labelled 'economically inactive'. A specific sub-group within the 'economically

inactive' category are singled out for separate analysis and these are homemakers; people of working age who are not employed as they stay at home to care for the family (children or elder relatives). This represents a significant sub-group in the context of motherhood and employment.

## **Aim**

This study analyses the relationship between non-employment and health among lone and couple mothers in three different family policy models. Furthermore, we investigate whether there are synergy effects between being a lone mother and non-employed on health in these different settings, and discuss the results related to policy and actual living conditions.

## **Data and methods**

### *Datasets*

National surveys based on a representative random sample of the population were used for analyses for each policy setting, identifying lone and couple mothers aged 25-59 years. For Britain we analysed data from the General Household Survey (GHS) (Office for National Statistics 2002). The GHS is a continuous, cross-sectional survey of household in Britain, administered by face-to face interviews to all adults aged 16 and over in the selected households. Data were pooled for the years 2000-2003, yielding 1573 lone and 5293 couple mothers. The response rate was between 67 and 72 %. For Italy we used data from the National Health Survey for the years 1999-2000 (Istat 2002) and 2004-2005 (Istat 2007), administered by both face-to-face interviews and self-complied questionnaires, on a sample representative of the non-institutionalised population. We identified 4031 lone and 38841 couple mothers. The response rate was 87 and 84 % respectively. For Sweden we analysed data from the Swedish Survey of Living Conditions (ULF), conducted by Statistics Sweden (Statistics Sweden 2006). The ULF is a continuous series of annual surveys on the welfare of the population, administered by face-to-face interviews, which draws a random sample of approximately 7,500 people from all permanent residents in Sweden, aged between 16 and 84

1 years. Data for the years 2000-2005 were pooled, 867 lone and 4260 couple mothers were  
2 identified. The response rate was between 75 and 78 %.

### 3 4 5 *Independent variable definitions*

6  
7  
8  
9 A mother was defined as a person who lives with at least one of her children aged less than 18  
10 years. A “*couple*” mother was defined as a mother who is either married or cohabiting and  
11 lives with her partner. A “*lone*” mother may or may not be living with other adults in the  
12 households but does not live with a partner.  
13  
14  
15

16  
17  
18 Age was divided into age groups: 25-34, 35-44 and 45-59.

19  
20  
21 Level of education was classified based on the international standard classification of  
22 education (ISCED) for highest attained level of education (UNESCO 1997). The national  
23 codes were classified into three categories using the ISCED-scheme. ISCED levels 1 and 2  
24 were grouped into “*low education*”, levels 3 and 4 into “*medium education*” and levels 5 and  
25 6 into “*high education*”.  
26  
27  
28  
29  
30

31  
32 Occupational class is based on current or last occupation, and respondents were classified into  
33 three groups; “*non-manual*”, “*manual*” and “*never worked*”. The last group includes mothers  
34 who could not be classified into any of the other groups.  
35  
36  
37  
38  
39

40 Employment status was classified into “*employed*” (including mothers who are employed part  
41 time/full time or work unknown hours or are self-employed), “*unemployed*” according to the  
42 ILO definition (unemployment is a count of jobless people who want to work, are  
43 available to work, and are actively seeking work) and “*economically inactive*” (all others).  
44 Mothers looking after the home were classified as “*homemakers*”, and were analysed  
45 separately from the economically inactive as they make up a large share of mothers in Britain  
46 and Italy. Swedish lone homemakers were few (n below 50), and therefore included in the  
47 economically inactive category. In the multivariate analyses (see table II and III), “*non-*

Having pre-school children may influence employment decisions for both lone and couple  
mothers, and perhaps more so for lone mothers. If there is no available/affordable childcare

1 working outside the home may be difficult. The definition of *pre-school children* was  
2 country-specific, according to the common age of starting school. For Britain this means  
3 children under the age of five, for Italy under the age of six and for Sweden children under the  
4 age of seven years.  
5  
6

7  
8  
9 Although not the focus of this study, we have included smoking, as an important health  
10 behaviour that is implicated in explanation of the observed social inequalities in health  
11 (Jarvis and Wardle 2006). *Smoking* status was coded as daily smoker vs not daily smoker.  
12  
13

### 14 15 16 *Dependent variable* 17

18  
19  
20 The outcome measure was self-rated health (SRH). SRH is recommended as a health indicator  
21 by WHO (Lundberg, Manderbacka et al. 2000) and is considered a good proxy of future  
22 morbidity and mortality (Benjamins, Hummer et al. 2004, Jylhä 2009). SRH has been shown  
23 to be useful both for use within countries and in country comparisons (Lundberg and  
24 Manderbacka 1996; Jylhä, Guralnik et al. 1998; Yngwe, Diderichsen et al. 2001). In British  
25 data, SRH was measured on a three-point scale, ranging from “*good*” to “*not good*”. The  
26 responses were dichotomized as “*good*” and “*poor health*” (comprising fair and not good  
27 health). In Italian, as well as in Swedish data, SRH was measured using a five-point scale  
28 ranging from “very good” health to “very poor” health. The responses were dichotomized into  
29 “*good health*” (comprising very good and good health) and “*poor health*” (comprising  
30 average, poor and very poor health). All mothers with a missing value on SRH were excluded  
31 from analyses.  
32  
33  
34

### 43 44 *Statistical analysis* 45

46  
47 Population characteristics of lone and couple mothers were calculated for each country using  
48 national survey data. Multivariate logistic regression models were fitted to evaluate the  
49 relationship between motherhood type and employment status, with poor health as outcome  
50 measure. In the first model we adjusted for age group. The second model additionally  
51 adjusted for education. Using educational level rather than current or last occupation as a  
52 measure for socio economic position in the regression model was judged as preferable since  
53 education precedes employment. The third model also adjusted for employment status. The  
54 fourth model adjusted for age group and daily smoking. The covariates included in the final  
55  
56  
57

64  
65

1 model were motherhood type (lone=1 versus couple mother=0), age (dummies of age groups;  
2 25-34, 35-44, 45-59, with the age group reporting best health among lone mothers as a  
3 reference in each country respectively, in all countries 25-34), level of education (dummies of  
4 education; low, medium and high, with high education as the reference category) employment  
5 status (non-employed=1 versus employed=0), smoking (daily smoker=1 versus not daily  
6 smoker=0). Since measures like SRH may be culturally biased (Jyhlä 2009) we studied the  
7 countries one by one, looking at the excess risk among lone mothers within countries (see  
8 Esser and Palme (2010) for a similar design). This is further motivated by the slight difference  
9 in how SRH was measured in Britain.  
10  
11  
12  
13  
14  
15  
16

17 For Italian data, weights were used to handle differences in sample strategies between the  
18 survey years. Proportion coefficients were obtained dividing the sample weights of the two  
19 data sets (1999-2000 and 2004-2005) by the product of the sum of the sample weights for  
20 corresponding frequencies.  
21  
22  
23  
24  
25  
26

27 Interaction effects on health between being lone and non-employed were assessed using the  
28 synergy index, according to Rothman's definition of interaction (Rothman and Greenland  
29 1998) using a SAS program developed by Lundberg, Fredlund, Hallquist and Diderichsen  
30 (Lundberg, Fredlund et al. 1996). The model investigates whether there are cases that only  
31 occur in the presence of joint exposure, i.e. the effect of one factor depends on the person's  
32 status of the other factor. Where there is departure from additivity of effects, the exposures  
33 may be dependent on one another. If the value for synergy exceeds 1.0 there is synergy.  
34  
35  
36  
37  
38  
39  
40  
41

42 The synergy index is given by:

$$43 \text{SI} = \frac{44 [\text{RR}_{11} - 1]}{45 [(\text{RR}_{10} - 1) + (\text{RR}_{01} - 1)]}$$

46  
47  
48  $\text{RR}_{11}$  is the relative risk (RR) among those who are exposed to both risk factors (here: non-  
49 employment and lone motherhood),  $\text{RR}_{10}$  and  $\text{RR}_{01}$  are the relative risks where only one of  
50 the risk factors are present, respectively.  $\text{RR}_{00}$  is the reference category, which is equal to 1.  
51 In this study, since we use cross-sectional data we use the odds ratio (OR) instead of RR. The  
52 results are obtained through logistic regression, controlling for age and level of education. The  
53 interaction analyses were made for lone and couple mothers who were non-employed vs.

15  
16 Following the framework for studying pathways to inequalities in health from the social  
17 context to health outcomes (Diderichsen, Evans et al. 2001; Fritzell, Ringback Weitoft et al.  
18 2007; Burstrom, Whitehead et al. 2010), we explored three principal explanations for health  
19 inequalities between non-employed lone and couple mothers; compositional factors,  
20 differential exposure to risk factors and finally, differential vulnerability to the same  
21 exposures.  
22

### 27 28 29 *Social characteristics and composition of lone motherhood and exposures to non-employment* 30 *in Britain, Italy and Sweden* 31

32  
33  
34 As presented in Table I, the composition of mothers varied between the countries. Lone  
35 motherhood was most common in Britain, where one in four mothers was lone. The median  
36 age of mothers and especially lone mothers was lowest in Britain (38 years for couple and 36  
37 years for lone) and highest in Italy (42 years for couple and 46 years for lone). Swedish lone  
38 mothers were more evenly distributed across the age groups. Unemployment was more  
39 common among lone than couple mothers in all three countries. Being in the labour force,  
40 whether employed or unemployed, was most common among Swedish lone mothers (77.4 %)  
41 and least common among British lone mothers (60.8 %). Only in Italy did lone mothers have  
42 higher labour force participation than couple mothers. Homemakers were a large group in  
43 Britain, and more frequent among lone than couple mothers. In Italy the opposite pattern was  
44 found. The economically inactive category was more frequent among lone mothers in all three  
45 countries.

64  
65

1  
2 In Italy, the largest relative differential in poor health between lone and couple mothers was  
3 found among homemakers. In Sweden it was among the economically inactive and in Britain  
4 among the employed.  
5  
6

7 There were some similarities between the countries in the composition of mothers by  
8 employment and occupation. In all countries, the employed lone mothers were more often had  
9 higher education, were more often non-manual than manual workers, and reported better  
10 health than did non-employed lone mothers. Also, it was less common for lone mothers with  
11 pre-school children to be employed than for couple mothers in the same situation.  
12  
13  
14  
15  
16

17  
18 The non-employed lone mothers in both Britain and Sweden were more likely than employed  
19 lone mothers to be young and have pre-school children (especially the British homemakers).  
20 The pattern in Italy differed from that in Britain and Sweden. Italian lone mothers who were  
21 homemakers or other economically inactive were more often older, smoked less and reported  
22 worse health than the employed or unemployed. Many of the Italian homemakers were in the  
23 oldest age group and had never worked. British couple mothers who were homemakers were  
24 predominantly non-manual, while the lone were mainly manual, and more prevalent in the  
25 younger age-groups.  
26  
27  
28  
29  
30  
31  
32

33  
34 Daily smoking was more common among non-employed lone mothers in Britain and in  
35 Sweden, while the employed (and unemployed) lone mothers in Italy reported the highest  
36 rates of smoking. In Sweden and Britain it was nearly twice as common for lone than couple  
37 mothers to smoke daily.  
38

43 **Table I about here**  
44

45  
46 *Do differences in exposure to non-employment between lone and couple mothers explain the*  
47 *risk of poor health?*  
48  
49  
50

51  
52 As there were differences in the social composition between the lone mothers who were  
53 employed and non-employed, we fitted logistic regression models modelling the odds of poor  
54 health for lone mothers compared to couple mothers, adjusting for these factors (see Table II).  
55 The regression analysis showed that the age adjusted odds ratios between motherhood type  
56 and poor health were highest in Sweden and lowest in Italy. Non-employment was indeed  
57

14 *couple mother?*  
15  
16  
17

18  
19 Lone mothers may be more vulnerable to non-employment in terms of health. In the  
20 interaction analyses (see Table III) we found examples of synergy effects, i.e. that there was  
21 an interaction effect of combining the exposures of being a lone mother and being non-  
22 employed, causing a higher risk of poor health than would be expected from a simple addition  
23 of these exposures, in all three countries, although not statistically significant for British lone  
24 mothers.  
25  
26  
27  
28  
29  
30

31  
32 **Table III about here**

33  
34  
35 Stratified analyses by presence of preschool children in the household, showed that the  
36 negative interaction effect for combining the exposures of being a lone mother and being  
37 outside the labour market was higher among British non-employed lone mothers with pre-  
38 school children (2.33, CI 0.97-5.60) compared to 0.98 (CI 0.68-1.42) for lone mothers with  
39 older children. In Sweden the pattern was the opposite, SI for non-employed lone mothers  
40 with pre-school children was 1.60 (CI 0.83-3.11) and 2.45 (CI 1.46-4.11) for lone mothers  
41 with older children. Italian data showed that SI for non-employed lone mothers with older  
42 children was 1.73 (CI 1.02-2.92) (the model with preschool children did not converge due to  
43 low number of lone mothers with preschool children).

## 56 **Discussion**

57  
58  
59 *Main results*  
60  
61  
62  
63  
64  
65

1 The prevalence, social composition and employment status of lone motherhood differed  
2 between the countries. Lone motherhood in both Britain and Sweden was associated with  
3 increased risk of poor health, while lone mothers in Italy did not have higher risk of poor  
4 health compared to couple mothers. Poor health was more prevalent among the non-employed  
5 mothers compared to those employed, in all countries.  
6  
7  
8  
9

10  
11  
12 Non-employment only marginally contributed to the excess risk of poor health among lone  
13 mothers found in Britain and Sweden. However, there were synergy effects for lone  
14 motherhood and non-employment, indicating a higher risk of poor health than would be  
15 expected from a simple addition of these exposures, in all countries. Patterns of synergy  
16 effects regarding lone mothers with pre-school children differed between the countries.  
17  
18  
19  
20  
21

#### 22 23 24 25 *Why increased risk of poor health among the non-employed lone mothers?* 26

27  
28  
29 The prevalence and age composition of lone mothers differed between the countries. The non-  
30 employed in Britain and Italy differed greatly in age. While Britain has a large share of young  
31 mothers, in Italy many of the non-employed were homemakers who were generally older.  
32  
33 Common to both groups is that they have difficulty in finding employment. The high  
34 employment rate in Sweden of women from all social groups is due both to the availability of  
35 childcare and the job opportunities in the large public service sector. Women's position in the  
36 labour market is affected by a range of social and labour market policies, not least by the  
37 provision of child care (Huber, Stephens et al. 2009). Indeed, as other studies have shown,  
38 having pre-school children (Gornick and Meyers 2003) and low education are both related to  
39 lower employment proportions among women (Lewis 2009). Looking specifically at mothers  
40 with pre-school children we found that the family policy context does have salience in the  
41 British and Swedish context, and appeared to be linked to the availability of child care. Thus,  
42 the risk of poor health was higher among British non-employed lone mothers with pre-school  
43 children (compared to having older children), while the pattern was the opposite for Swedish  
44 lone mothers. Combining employment and lone parenthood may be difficult due to the time  
45 strain it imposes, and lone mothers may be confined to non-employment in spite of a desire to  
46 work. Besides providing material resources, employment is an important aspect of  
47 motherhood, also in England (Grant 2009). In line with the dual earner family policy model,

65

in Sweden, working is the morally right thing to do for mothers (Björnberg 1997, Fritzell, Bakshi et al. 2011). However, often the jobs available to lower educated women or (as in the case of Grant's study, 2009) women who are living in disadvantaged neighbourhoods, are low paid jobs that lack flexibility in working hours. This lack of flexibility in work hours, as well as lack of flexibility in availability of day care may prevent lone mothers from working (Fritzell, Bakshi et al. 2011).

Health behaviour may also explain part of the statistical association between lone motherhood, non-employment and health. Smoking was nearly twice as common among lone than couple mothers in Britain and Sweden, and most prevalent among the non-employed. In Italy, differences in smoking between lone and couple mothers were smaller, and the lowest rates were reported among the non-employed mothers. In the British context, smoking is strongly related to poverty and disadvantage (Graham 2007). Experiences of disadvantage such as childhood poverty, leaving school early, moving into early parenthood are cumulative and lead to an increased risk of being a smoker (Graham 2007). Also in Sweden, smoking is linked to adversity (Ali, Chaix et al. 2009). In Italy, by contrast, smoking has recently been taken up by women and is more common among the higher educated, but a shift is taking place among young women where smoking is more common among the less educated group (Federico, Costa et al. 2007).

The reasons for the synergy effects between lone motherhood and non-employment may be two-fold. Firstly, there is *health selection* into non-employment (Jusot, Khlal et al. 2008), and this may be especially so for lone mothers. Secondly, the *health impact* of not having an income from gainful employment may be especially damaging for lone mothers. Both of these, in turn, may vary with the societal context.

The welfare arrangements and family policy in Sweden are encompassing and comparatively generous. In spite of this, lone mothers without employment fare relatively worse in relation to other mothers in Sweden. This may imply a stronger health selection out of employment in Sweden compared to Britain, where the employment rate was lowest and where (lone) mothers have not been expected to work to the same extent. Employment may also have a different meaning and a different association to health in the three countries. While both Britain as part of the Market-oriented family policy model, and Italy as part of the Traditional-family policy model, have actively promoted mothers to stay at home and look

1 after children – putting women with children apart from the rest of the workforce, in Sweden  
2 there is an employment imperative for all citizens alike. The findings concerning the poor  
3 health of the unemployed are in line with findings of Bambra and Eikemo (2009), who  
4 interpreted their finding as indicating that the negative health effects of unemployment are  
5 particularly strong for women in the Scandinavian and Anglo-Saxon welfare regimes (where  
6 we find Sweden and Britain respectively), in comparison with the Southern welfare states  
7 (where Italy is included). Our analyses focus on the “early days” of the policy changes in  
8 Britain that took place during the 1997-2010 Labour government aimed at facilitating  
9 employment for lone mothers. It will be important to follow up what effect these changes in  
10 policy context, have had for health and living conditions for lone mothers.  
11

13  
14  
15  
16  
17  
18  
19

20 The health impact of not having an income from gainful employment may be especially  
21 damaging for lone mothers. Financial strain has been shown to be an important explanation  
22 for the excess risk of ill health of lone mothers in comparison to couple mothers (Hope, Power  
23 et al. 1999; Fritzell and Burström 2006; Cooper, Bebbington et al. 2008). Evidence from the  
24 Luxembourg Income Study (LIS Inequality and Poverty Key Figures 2010) 2004 and 2005  
25 indicated that the poverty rates (below 50% of median income) are high among children  
26 living in lone mother families, and that they vary between the countries; for Britain 32.1%, for  
27 Italy 29.8%, and for Sweden 10.4 % . Additional analyses of European Social Survey (ESS)  
28 data (Survey 2009) from rounds 1 and 2 conducted between 2002 and 2006, indicated that  
29 financial problems were considerably more common among the non-employed lone mothers  
30 than among the employed in all three countries (data not shown). Furthermore, in terms of  
31 social exclusion, analyses from the ESS data show that the non-employed lone mothers stood  
32 out as more disadvantaged than employed lone mothers, and in relation to non-employed  
33 couple mothers. This is in line with the reasoning of Sen (2000) who argues that besides from  
34 being excluded from economic opportunities it may also be problematic for jobless people to  
35 participate in community life.

50  
51 Swedish lone mothers have experienced a deterioration of living conditions and health during  
52 the 1990s. The link between employment and health has become stronger (Fritzell, Ringback  
53 Weitoft et al. 2007), and the present study shows that health was strongly associated with  
54 employment also in 2000-2005. Still, the comparatively low level of poverty among families  
55 with children in Sweden (and other Nordic countries) is likely to be due both to the relatively  
56 higher level of benefits received and the dual-earner model facilitating mothers’ employment  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 (Ferrarini 2006). Replacement rates and entitlements to benefits are of potential significance  
2 for the health of the non-employed. A study analysing mental health among the unemployed  
3 in Sweden, Ireland and Britain suggested that higher levels of benefits such as in Sweden  
4 improve the mental well-being among the unemployed (Nordenmark, Strandh et al. 2006).  
5  
6

7  
8  
9 Seemingly, in Italy there was only a small excess risk for less than good health compared to  
10 couple mothers. This may however be influenced by family values, social stratification and of  
11 different routes into lone motherhood. Mothers can be lone parents for many reasons. Family  
12 values regarding divorce, separation and unmarried parenthood in combination with  
13 possibilities of making a living as a lone mother - what Orloff (1993) calls “capacity to form  
14 an independent household” - influence the composition and the size of the group lone  
15 mothers. A previous study (Burstrom, Whitehead et al. 2010) showed that the most common  
16 route into lone motherhood in Italy was becoming a widow, while divorce/separation or being  
17 single from the start was by contrast the most common route in Sweden and Britain. In Italy,  
18 there are no unemployment benefits for those who have not yet entered the labour market, and  
19 there is no national last resort safety net for the poor (Naldini and Saraceno 2008).  
20

21 Accordingly, in Italy divorce and separation is most common among women with high social  
22 position; well educated women with attachment to the labour market (Solera 1998; Istat 2008;  
23 Burstrom, Whitehead et al. 2010) and only in Italy was employment more prevalent among  
24 lone mothers compared to couple mothers.  
25  
26

29  
30  
31  
32  
33  
34  
35  
36  
37  
38 Researchers have argued that Italy is experiencing the emancipation of women resulting in an  
39 increase in the numbers of lone mothers (Trifiletti, Pratesi et al. 2001). Should the anticipated  
40 development continue and the composition change to include all social groups, it may result  
41 in increased differentials in health between lone and couple mothers in Italy, and in particular  
42 among the youngest and lowest skilled/educated mothers who are known to be  
43 disproportionately hit by unemployment. As Korpi, Ferrarini and Englund (2011) note, it is  
44 the women with working class background that are at higher risk of non-employment in all  
45 types of family policy dimensions. Women with higher education are in the labour force to a  
46 larger extent irrespective of family policies, as seen in this study particularly in the case of  
47 Italian lone mothers. The dual earner family policy model however does better in including  
48 other social groups in the labour market, as seen in the Swedish employment proportions for  
49 mothers.

## *Limitations*

1  
2  
3  
4 The cross sectional design of this study does not allow for conclusions on the causality of the  
5 associations we find. We used large national household surveys, pooling several survey years  
6 to yield statistical power and enable sub group analysis of the non-employed. Data  
7 comparability is a potential pitfall in all cross-national research. Issues concerning sample  
8 frame and country specific variables may limit the comparability between countries using  
9 national surveys. We were not able to analyse financial problems or lack of social support for  
10 all three countries, known to be prevalent risk factors among the non-employed lone mothers.  
11 Analysing data on national level may also conceal regional differences, for instance labour  
12 market participation for mothers varies from 60% in the northern areas to 20% in the southern  
13 areas of Italy (Del Boca and Vuri 2007). Levels of, as well as entitlements to, transfers also  
14 differ between regions in Italy.  
15

17  
18  
19  
20  
21  
22  
23  
24

25 As the response rate is generally lower among those with lower socio-economic position, and  
26 in poor health status are less likely to participate in surveys (Lorant, Demarest et al. 2007), it  
27 is possible that the excess risk of less than good health among non-employed lone mothers is  
28 underestimated in this study.  
29  
30  
31  
32  
33

34 Reporting of levels of self-rated health may be culture specific. These differences may be real  
35 differences in objective health status, or differences in levels of knowledge that underlie self-  
36 rated health or finally differences in how personal evaluations of health are made (Jyhlä  
37 2009). The absolute prevalence levels of poor health, therefore, were not compared between  
38 countries. Comparing sub-groups within countries, we may use the absolute prevalence rates.  
39 Large relative differences between lone and couple mothers within each employment status  
40 group were found in Sweden. The large relative inequalities as well as the comparatively low  
41 absolute levels of poor health found in Sweden are consistent with other studies (Lahelma and  
42 Lundberg 2009).  
43

47  
48  
49  
50  
51

52 Although causality cannot be inferred, this study suggests potential explanations behind the  
53 poor health of the non-employed and identifies non-employment as a structural issue with  
54 implications for lone mothers' health.  
55  
56  
57  
58  
59

## *Conclusion*

1 Being non-employed was relatively worse for lone than couple mothers' health, in all three  
2 countries studied. Lone motherhood and non-employment are dynamic states. From a public  
3 health perspective, this makes the poor health of non-employed lone mothers all the more  
4 important as it affects many women and their children, and potentially increasingly so, since  
5 lone motherhood is an increasing phenomenon. Theoretically, it could be remedied as family  
6 policy is shaped by politics. Further work would benefit from a specific focus on lone fathers.
